Abstract. The role of convection in introducing aerosols and promoting the formation of new particles to the upper troposphere has been examined using a cloud-resolving model coupled with an interactive explicit aerosol module. A baseline simulation suggests good agreement in the upper troposphere between modeled and observed results including concentrations of aerosols in different size ranges, mole fractions of key chemical species, and concentrations of ice particles. In addition, a set of 34 sensitivity simulations has been carried out to investigate the sensitivity of modeled results to the treatment of various aerosol physical and chemical processes in the model. The size distribution of aerosols is proved to be an important factor in determining the aerosols' fate within the convective cloud. Nucleation mode aerosols (here defined by $0 \leq d \leq 5.84$ nm) are quickly transferred to the larger modes as they grow through coagulation of aerosols and condensation of H_2SO_4. Accumulation mode aerosols (here defined by $d \geq 31.0$ nm) are almost completely removed by nucleation (activation of cloud droplets) and impact scavenging. However, a substantial part (up to 10% of the boundary layer concentration) of the Aitken mode aerosol population (here defined by $5.84\,\text{nm} \leq d \leq 31.0$ nm) reaches the top of the cloud and the free troposphere. These particles may continually survive in the upper troposphere, or over time form ice crystals, both that could impact on the atmospheric radiative budget. The sensitivity simulations performed indicate that critical processes in the model causing a substantial change in the upper tropospheric number concentration of Aitken mode aerosols are coagulation of aerosols, condensation of H_2SO_4, nucleation scavenging, nucleation of aerosols and the transfer of aerosol mass and number between different aerosol bins. In particular, for aerosols in the Aitken mode to grow to CCN size, coagulation of aerosols appears to be more important than condensation of H_2SO_4. Less important processes are dry deposition, impact scavenging and the initial vertical distribution and concentration of aerosols. It is interesting to note that in order to sustain a vigorous storm cloud, the supply of CCN must be continuous over a considerably long time period of the simulation. Hence, the treatment of the growth of particles is in general much more important than the initial aerosol concentration itself.

1 Introduction

Atmospheric aerosols play a central role in cloud formation and cloud development, as particles constitute surfaces for liquid and ice particles to form. Both observational and numerical modeling studies have shown that an increase in aerosol concentrations due to anthropogenic emissions may result in optically thicker clouds and altered rainfall rates and characteristics (Twomey, 1974; Albrecht, 1989; Rosenfeld, 1999, 2000; Andreae et al., 2004; Koren et al., 2004). Most previous model studies in this field have focused on low-level stratiform clouds, as they cover a large part of the earth compared to other cloud types and thus are thought to have a larger impact on the Earth's climate through a change in aerosol properties. However, the few studies available on anthropogenic aerosol effects on both convective clouds and ice clouds indicate a high sensitivity of the cloud characteristics to the boundary layer aerosol concentration, and thus there is a need for additional research (Andronache et al., 2002; Clement et al., 2002; Phillips et al., 2002; Kärcher and Lohmann, 2003; Nober et al., 2003). Recently analyzed satellite data over the Amazon basin indicate that scattered cumulus cloud cover can be reduced from 38% in clean conditions to 0% for heavy smoke conditions (Koren et al., 2004). In addition, in-situ data collected over the same region shows that the onset of precipitation is increased from 1.5 km above cloud base in pristine clouds to more than 5 km in polluted clouds and 7 km in the most extreme form of smoky

clouds (Andreae et al., 2004). However, elevating the onset of precipitation under smoky conditions results in more vigorous storm clouds (higher wind speed, larger ice hydrometeors), and the net effect on the area amount of precipitation remains unknown.

Convective clouds provide an efficient mechanism for transporting material from the surface to the upper troposphere. Although observational data in the upper troposphere are still limited, the few measurements available all indicate the existence of high concentrations of small particles (e.g. Clarke, 1992, 1993; Nyeki et al., 1999; Ström et al., 1999; Clarke and Kapustin, 2002; Petzold et al., 2002; Schröder et al., 2002; Twohy et al., 2002; Hermann et al., 2003; Minikin et al., 2003), possibly due to the vertical transport related to deep convection. In addition, with sufficiently low temperature, high relative humidity, and relatively high concentrations of aerosol precursors; the outflow regions of convective clouds are likely areas for new aerosols to form, adding even more particles to the upper troposphere (Zhang et al., 1998; Clarke et al., 1999; Ström et al., 1999; Clement et al., 2002). However, there is still a major uncertainty regarding which chemical compounds are most important in the aerosol nucleation process, and to what extent these gases are scavenged by the heavy precipitation associated with a storm cloud.

Explicit modeling of aerosol-cloud interactions in mesoscale cloud systems is a computationally expensive task as there are numerous processes with different temporal and spatial scales that need to be considered in simulating the cloud development; the physical and chemical properties including the size distributions of aerosols and cloud droplets, as well as the interactions among these particles. Given this broad range of conditions, most previous model studies of aerosol-cloud interactions have used simplified descriptions of the cloud processing, usually by considering adiabatic parcel models (de Reus et al., 1998; Kulmala et al., 1998a; Clement et al., 2002). Zhang et al. (1998) incorporated a two-moment aerosol model into a two-dimensional cloud and sulfate chemistry model to simulate the effects of clouds on aerosol redistribution and production in cumulonimbus clouds. They found that the nucleation rate after cloud dissipation in the upper troposphere increased by one order of magnitude compared to the nucleation rate before cloud formation. Jacobson (2003) developed a one-dimensional gas-aerosol-cloud module suitable for implementation in global or regional scale three-dimensional models. Results using this module suggest that if aerosol number is considered (i.e. in general small particles), impact scavenging is a more important removal mechanism than nucleation scavenging, removing more than 42% of the total number of particles. On the other hand, if aerosol mass is considered (i.e. in general large particles), nucleation scavenging is clearly the dominant aerosol removal process. These findings indicate that medium-size particles may be most likely to survive transport within a convective cloud without being scavenged by precipitation.

In order to simulate convective cloud transport along with cloud processing of aerosols, we have coupled a three-dimensional cloud-resolving model based on previous model work (Wang and Chang, 1993a; Wang and Crutzen, 1995; Wang and Prinn, 2000) with an interactive explicit aerosol module (Wilson et al., 2001). Observational data as well as weather center reanalyzed data have been used to initialize the model simulations. To evaluate the model, the results are compared with observed concentrations of aerosols and certain key chemical species, particularly in the upper troposphere (Ström et al., 1999). In this paper, only a brief evaluation of the 2-D version of the model is performed. A more detailed comparison is presented in a sequential paper (Ekman et al., in preparation, 2004[1]) using the 3-D version of the model. The main purpose of this research is not only to simulate the formation and transport of aerosols within as well as surrounding a convective cloud, but also to examine the sensitivity of the aerosol concentration and the properties of the cloud to various aerosol physical and chemical processes.

In this paper, we first describe the implementation of the explicit aerosol module into the cloud-resolving model. The discussions of the modeled features in dynamics, microphysics, and chemistry of the observed storm and a brief comparison between modeled and observed results are given following the model description. We then focus on the results of the sensitivity simulations aiming at revealing the dependencies of the aerosol module on various physical and chemical processes as well as initial aerosol concentration and chemical composition. The discussions and conclusions are given in the last section.

2 Model

2.1 Cloud resolving model

The cloud-resolving model (CRM) used in this study is an improved version of the model developed by Wang and Chang (1993a) with a full integration of the dynamics-physics and chemistry sub-models (Wang et al., 1995; Wang and Prinn, 2000). The dynamics-physics module consists of non-hydrostatic momentum equations, the continuity equations for water vapor and air mass density, the thermodynamic equation, and the equation of state (Wang and Chang, 1993a). Also included are prognostic equations for the mixing ratios as well as number concentrations of cloud droplets, raindrops, ice crystals and graupel particles. The microphysical transformations are formulated based on a "two-moment" scheme incorporating the size spectra of particles (Wang and Chang, 1993a; Wang et al., 1995). A δ-four-stream radiation module based on Fu and Liou (1993) is incorporated in

[1]Ekman, A. M. L., Wang, C., and Ström, J.: Explicit simulation of aerosol physics in a cloud-resolving model: Aerosol transport and processing in the free troposphere, in preparation, 2004.

the model and it uses predicted concentrations of gases (including H_2O and O_3) and hydrometeors to calculate radiative fluxes and heating rates.

Cloud droplets in the atmosphere are formed on cloud condensation nuclei (CCN). In the CRM, the number of particles available for cloud droplet nucleation is predicted using the aerosol module (cf. Sect. 2.2). The number of ice nuclei (IN) is in the present model version not calculated using the explicit aerosol module. An initial IN concentration is assumed (cf. Sect. 3), and the IN are advected in the model and removed by ice particle formation, but the IN are not affected by coagulation of aerosols, condensation of H_2SO_4 or other aerosol physical processes.

The chemistry sub-module predicts atmospheric concentrations of 25 gaseous and 16 aqueous (in both cloud droplets and raindrops) chemical compounds including important aerosol precursors such as sulfate and nitrate, undergoing more than 100 reactions as well as transport, and microphysical conversions. A module of heterogeneous chemistry on ice particles has been developed and is included in the present version of the model (Wang, submitted, 2004a [2], b[3]). This module calculates surface uptakes of several key chemical species including HNO_3, SO_2, H_2O_2 and CH_3OOH by ice particles.

The cloud-resolving model has been used in studies on dynamics, microphysics, and chemistry of continental deep convection (e.g. Wang and Chang, 1993a, b; Wang and Crutzen, 1995) and oceanic deep convection over the Pacific (Wang et al., 1995; Wang and Prinn, 1998, 2000). Results obtained using the model have also been compared with available observations including aircraft, radar, and satellite data. The spatial resolution of the model can be flexibly set, a horizontal grid interval of 2 km and a vertical grid interval of 400 m are used in this study.

2.2 Aerosol module

The evolution in time and space of aerosols consisting of sulfate, organic carbon, black carbon and mixtures thereof is described using a multi-modal aerosol model (Wilson et al., 2001). In this paper, we mainly describe our revision of this module and the additional improvements needed to incorporate the aerosol module into our cloud-resolving model.

In our version of the aerosol module, five different modes are used to represent the aerosol population (Table 1). Among these five modes, carbon originating from both fossil fuel combustion and biomass burning is considered. The size distribution within each aerosol mode is assumed to be log-normal and is described by three parameters: number, mass,

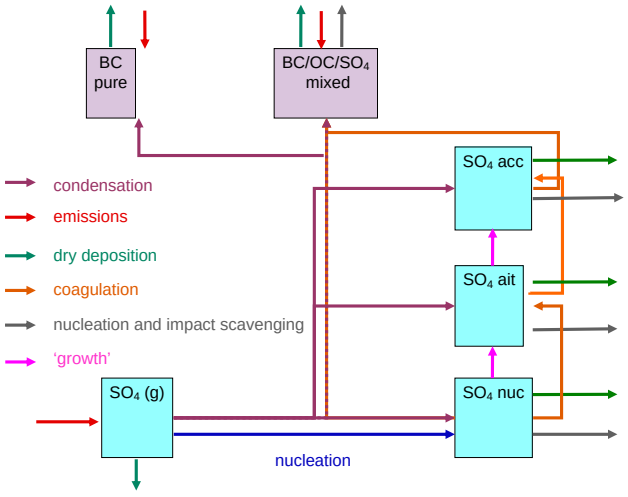

Fig. 1. Schematic picture of processes included in the aerosol model (after Wilson et al., 2001).

and standard deviation (σ_{std}, cf. Wilson et al., 2001). Figure 1 shows a schematic picture of the different aerosol processes included in the model. Note that in this study, mainly to reduce the computational burden, the standard deviations are prescribed. Dry deposition of aerosols is calculated according to Langner and Rodhe (1991) using the dry deposition velocities specified in Pruppacher and Klett (1997) and Wilson et al. (2001). In the default version of the model, due to the short integration time, emissions of both carbonaceous and sulfuric aerosols are set to zero. Therefore, carbonaceous aerosols have no additional sources other than the given initial loadings during the model integration. The continuous source in addition to the given initial loading of the whole sulfuric aerosol population (three modes) is the nucleation of new sulfate aerosols from H_2SO_4 and H_2O.

New particle formation via binary H_2O-H_2SO_4 nucleation is described using the parameterization developed by Kulmala et al. (1998a). The condensation coefficient as well as the intra- and inter-modal coagulation coefficients for each aerosol mode is determined from the theory of Fuchs (1964), using the geometric mean radius of each mode. Intra-modal coagulation leads to a reduction of the number of the mode but not of the mass, whereas inter-modal coagulation leads to a reduction of the number and mass of the smaller mode and an increase of the mass of the larger mode. For the pure sulfate modes, conversions are also enforced when the upper "tail" of the mode grows beyond the prescribed size limit for a given mode (cf. Table 1). When the number fraction of aerosols located above the size limit of a given mode exceeds 5% of the total in this mode, then 5% of the number of aerosols is reallocated to the adjacent mode (together with the corresponding amount of mass). To estimate when this transfer should be performed, we assume a log-normal

[2)] Based upon values given in Fig. 17-17 in Pruppacher and Klett (1997).

distribution for each aerosol mode, and compare the modeled mass weighted average diameter within each mode (diameter of average mass) with the theoretical diameter of the average mass for when the "tail" contains 5% or more of the total aerosol number.

The activation of a drop at a certain supersaturation depends on the composition of the solute. Only a part of the aerosols in an aerosol size bin may be activated. Consider the simplified Köhler equation (e.g. Pruppacher and Klett, 1997)

$$S_{v,w} = 1 + \frac{A}{a} - \frac{B}{a^3}, \tag{1}$$

where $S_{v,w}$ is the saturation ratio, a is the droplet radius and

$$A = \frac{2M_w\sigma_{w/a}}{RT\rho_w}, \tag{2}$$

$$B = \frac{3\upsilon m_s M_w}{4\pi M_s \rho_w}. \tag{3}$$

Here, M_w is the molecular weight of water and M_s is the molecular weight of the salt, $\sigma_{w/a}$ is the surface tension of water with respect to air, R is the universal gas constant, T is temperature, ρ_w is the density of water, υ is the number of ions into which a salt molecule dissociates in water and m_s is the mass of the salt.

By taking the first derivative of Eq. (1), the critical radius that corresponds to the critical saturation ratio for drop activation can be written as:

$$a^* = \sqrt{\frac{3B}{A}}. \tag{4}$$

The critical saturation ratio S^* is then obtained by inserting a^* back into Eq. (1)

$$S^* = 1 + \frac{2}{3}\sqrt{\frac{A^3}{3B}}. \tag{5}$$

The dry particle radius R is related to the variable B and we can find the critical activation radius R^*:

$$R^* = A\left[\frac{4M_s\rho_w}{27M_w\rho_s\upsilon_s(S-1)^2}\right]^{1/3}, \tag{6}$$

where ρ_s is the density of the salt, υ_s is the van't Hoff dissociation coefficient (in the simulations set to 2) and S is the environmental saturation ratio. For any aerosol size bin that has R^* within its boundaries ($R_{min}<R^*<R_{max}$), the bin must be split so that only particles with radius larger than R^* are activated. The total number of aerosols activated can be obtained by integrating the distribution function from R^* to R_{max}. Only pure sulfate aerosols and mixed aerosols are considered to constitute CCN. In many model studies, a simplified empirical relationship is used to describe droplet activation (e.g. Pruppacher and Klett, 1997):

$$N_{CCN} = CCN \cdot s_{v,w}^k, \tag{7}$$

where N_{CCN} is the number of activated CCN, $s_{v,w}$ is the supersaturation (%) and k is a constant varying for maritime and continental air. A sensitivity simulation is conducted to compare this traditional parameterization of aerosol activation with the description based on Köhler theory.

The activation of droplets determines the number of aerosols that are scavenged via nucleation scavenging. Another path for scavenging of aerosols is through collision with falling raindrops, graupel or ice crystals, i.e. the precipitation (impact) scavenging. The collision efficiency E in this case is by definition the probability of collisions between an aerosol and a precipitating droplet in a geometric volume swept out by the precipitating droplet in a given time interval (the droplet's effective cross-sectional area multiplied by the effective fall speed of the droplet with respect to the fall speed of the aerosol; Pruppacher and Klett, 1997). To theoretically determine E is complicated since the aerosol size varies over orders of magnitude and because the large raindrop size results in complicated flow patterns (drop oscillations, wake creation, eddy shedding, etc.). Pruppacher and Klett (1997) present an overview of the problem. The efficiency of Brownian diffusion induced particle-particle interactions decreases rapidly with increasing particle size and is thus the most important removal process for small particles (diameter $<0.2\,\mu$m). Inertial impaction and interception increase in importance as the aerosol size increases. These processes are most important for particles with diameters larger than $1\,\mu$m. The previous arguments indicate that whereas there are efficient removal processes for small and large particles, the collision efficiency for particles in the 0.1 to $1.0\,\mu$m size range is relatively small. As a first attempt to simulate the variability of impact scavenging with aerosol size, different values of E for the different aerosol bins in the model are defined (Table 1). A simulation using constant E equal to 0.1 (and only for accumulation mode aerosols) is included as a sensitivity study (cf. Table 2).

Both number concentration and mass mixing ratio of the five aerosol modes, i.e. all together 10 variables, are incorporated in the cloud-resolving model as prognostic variables undergoing transport, mixing, dry deposition, and nucleation as well as impact scavenging besides aerosol microphysical processes. The advection scheme used to calculate the transport of these aerosol variables is the same revised Bott scheme as developed in Wang and Chang (1993a). For the mixed mode, the ratio between BC, OC and SO_4 is assumed to be constant during the simulation.

3 Observed case and initial model conditions

The selected case to simulate is a cumulonimbus cloud with extended anvil over northern Germany, observed during the Stratosphere-Troposphere Experiment by Aircraft Measurements (STREAM) on 29 July 1994 (Ström et al., 1999). Convection was initiated as cool air from the Atlantic Ocean was advected towards Western Europe after several weeks of stagnant weather with clear skies, high temperatures and weak winds. During the preceding high-pressure period, a build-up of high boundary layer concentrations of aerosol particles, CO and O_3 had occurred. Several smaller groups of thunderstorms were formed along the cold front, and the aircraft measurements were conducted along a cross-section through the center of one of these storm clouds.

During the measurement flight, particles smaller than $1\,\mu$m diameter were sampled and counted using two TSI-3760 CPCs with lower cutoffs at 0.007 and $0.018\,\mu$m diameter, respectively. Note that the former cutoff of the particle counter is about $0.0015\,\mu$m smaller than the upper limit of size of what is termed "the Aitken mode sulfate aerosol" in our model. A counterflow virtual impactor (CVI) was used to sample cloud particles larger than $\sim 5\,\mu$m aerodynamic diameter. Water vapor was measured using a Lyman-α absorption hygrometer and observations of carbon monoxide and ozone mixing ratios were performed using the laser diode technique and chemiluminescence technique, respectively. The aircraft measurements were carried out in the anvil region of the storm. The research aircraft entered the cumulonimbus cloud at approximately 14:36 UTC at an altitude of $\sim$10.4 km. The aircraft flew a distance of $\sim$260 km across the frontal zone before leaving the cloudy air at about 15:03 UTC. In situ data from this level are presented in Fig. 5 in Ström et al. (1999).

The meteorological part of the CRM simulation is initialized using analyzed 3-dimensional initial data fields of pressure, temperature, winds and specific humidity obtained from the National Centers for Environmental Prediction (NCEP). Horizontally interpolated fields of NO_2, O_3 and SO_2 obtained from surface observations conducted by the Co-operative Programme for Monitoring and Evaluation of the Long-Range Transmission of Air Pollutants in Europe (EMEP, Hjellbrekke and Hanssen, 1998) are used to initialize the chemistry module. There are no observations of gaseous HNO_3 or H_2SO_4 available from EMEP. Initial concentrations of these compounds are instead obtained by combining results from previous simulations using the CRM (Wang and Chang, 1993a; Wang and Crutzen, 1995) and measured particulate concentrations of NO_3^- and SO_4^- from EMEP. Vertical profiles of all chemical compounds are prescribed as to decrease with height except for O_3, which is based on previous work.

For Aitken, black carbon, and mixed mode aerosols, a horizontally constant surface concentration of $50\,\mathrm{cm}^{-3}$ is assumed initially. The surface concentration of accumulation mode aerosols is set to be $500\,\mathrm{cm}^{-3}$. For ice nuclei particles (IN), the initial surface concentration is set to be $100\,\mathrm{cm}^{-3}$. These aerosol concentrations are representative for what may be observed in urban continental air (Seinfeld and Pandis, 1998). All aerosol concentrations are initially prescribed to decrease with height as a function of air density (surface concentration multiplied by $[\rho_{level}/\rho_{surface}]^3$, cf. Fig. 2). This type of vertical dependence is in fairly good agreement with the observations by Schröder et al. (2002) and Petzold et al. (2002). The initial mass concentration for each mode is calculated by assuming spherical particles with a density of $1.7\,\mathrm{g\,cm}^{-3}$ and a radius of 6.29 nm for the Aitken mode and

Table 2. Summary of sensitivity simulations conducted using the CRM.

Simulation number	Simulation name	Characteristics
1	R	Reference simulation
2	A1	No coagulation of aerosols
3	A2	No coagulation, no condensation of H_2SO_4 on aerosols
4	A3	No condensation of H_2SO_4 on aerosols
5	B1	No dry deposition of aerosols
6	B2	10 times higher dry deposition velocity for all aerosols
7	C1	Constant collision efficiency constant
8	C2	Collision efficiency multiplied by 2.
9	C3	Collision efficiency divided by 2.
10	C4	No impact scavenging of aerosols
11	C5	Impact scavenging of BC included (in same manner as for acc. mode SO_4)
12	C6	Lower limit of impact scavenging (cf. Table 1)
13	C7	Higher limit of impact scavenging (cf. Table 1)
14	D1	Aerosol initial number concentration (but not mass) multiplied by 2 throughout the whole model domain
15	D2	Aerosol initial number concentration (but not mass) divided by 2 throughout the whole model domain
16	D3	Constant initial aerosol concentration throughout the whole model domain (surface concentration used for all aerosols, instead of decreasing concentration with altitude scaled by density)
17	D4	Aerosol initial mass concentration multiplied by 2 throughout the whole model atmosphere
18	D5	Aerosol initial mass concentration divided by 2 throughout the whole model atmosphere

485 nm for the accumulation, mixed and black carbon modes. The nucleation mode aerosol concentration is assumed to be zero at the beginning of the simulation.

4 Results

In order to evaluate the behavior of the aerosol module incorporated into the cloud-resolving model and to explore the dependencies of this module on various physical and chemical processes as well as on initial aerosol concentrations and chemical compositions, we have designed 34 sensitivity simulations. These sensitivity simulations, targeting various physical and chemical parameters or processes, are categorized into 8 groups, hereafter labeled as A1 to H4 (cf. Table 2).

To achieve computational efficiency, we make use of the two-dimensional version of our model in the sensitivity simulations. Results obtained using the 2-D version of the model may slightly differ compared to the 3-D-simulation results (not shown in this paper), as the 2-D model version only simulates the cloud development along a cross-section of the convective cloud. For example, a comparison between the two model versions shows that the depth and the extension of the simulated anvil are not identical. However, for examining the sensitivity of the model this difference should not be of major importance.

The 2-D simulations are carried out over a 150×50 grid domain, covering 300 km horizontally and 20 km vertically. The 2-D chemical compound and meteorology fields used for the initialization of the model are cross-sections extracted

Table 2. Continued.

Simulation number	Simulation name	Characteristics
19	D6	Altered vertical slope of initial aerosol distribution (surface concentration multiplied by $(\rho_{level}/\rho_{surface})^{1.5}$ instead of $(\rho_{level}/\rho_{surface})^{3}$)
20	D7	Initial Aitken number concentration multiplied by 100 throughout the whole model domain
21	D8	Initial BC number concentration multiplied by 10 throughout the whole model domain
22	E1	Emperical nucleation scavenging parameterization (cf. Eq. 5)
23	E2	10 times larger critical radius (cf. Eq. 4)
24	E3	10 times smaller critical radius (cf. Eq. 4)
25	E4	Halved nucleation scavenging over the whole model domain
26	E5	SO_4 used for aerosol density instead of $(NH_4)_2SO_4$ (in Eq. 4)
27	F1	Aerosol nucleation rate decreased by a factor of 2 over the whole model domain
28	F2	Aerosol nucleation rate decreased by a factor of 10 over the whole model domain
29	F3	Aerosol nucleation rate increased by a factor of 10 over the whole model domain
30	G1	10 times higher initial H_2SO_4 concentration (up to 4 km altitude)
31	G2	10 times lower initial H_2SO_4 concentration (up to 4 km altitude)
32	H1	No transfer of aerosols between the modes
33	H2	2 times larger radius for transfer (cf. Sect. 2.2)
34	H3	2 times smaller radius for transfer (cf. Sect. 2.2)
35	H4	10% transfer of number instead of 5% (cf. Sect. 2.2)

from the thermodynamically most unstable area of the previously described 3-D initial fields (cf. Fig. 3). Open boundary conditions are applied for all variables, i.e. the normal influx to the model domain is equal to zero. Starting time is 12:00 UTC and the simulation is integrated for 3 h. Each time step is 5 s.

4.1 Reference simulation

A reference run was first designed for the sensitivity study. The purpose of this reference run is mainly to provide a "baseline" result that is in agreement with observational data for comparison with the rest of the sensitivity tests.

The characteristics of the simulated storm development are displayed in Fig. 4. Figure 5 shows the 2-dimensional distribution of various model parameters after three hours of simulation. Available observed maximum values at ∼10.4 km of cloud water content (CWC), crystal number density (CND), condensation nuclei (radius >7 nm, CN), and mixing ratios of CO and O_3 are indicated in the figures. Modeled maximum values at 10.4 km of CWC, CND, CO and O_3 differ less than 20% from the observations. Note that modeled and observed parameters at the same altitude level may not correspond exactly to each other; they should rather be considered as representative values of the cloud anvil.

As mentioned in Sect. 3, the weather before the passage of the cold front on 29 July had given rise to enhanced boundary layer concentrations of aerosol particles, CO and O_3. Figure 5d displays that high concentrations of Aitken mode aerosol particles are rapidly transported from the surface up to the free troposphere within the convective cloud. The simulated concentration at 10.4 km altitude is about two times higher than the observed one. However,

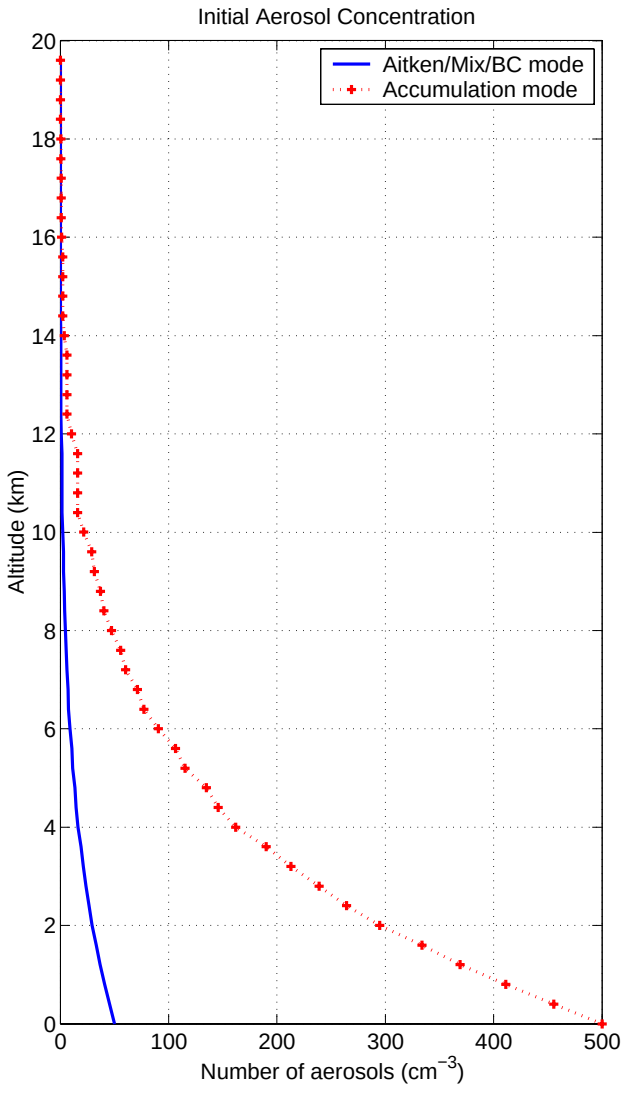

Fig. 2. Vertical profile of initial aerosol concentration.

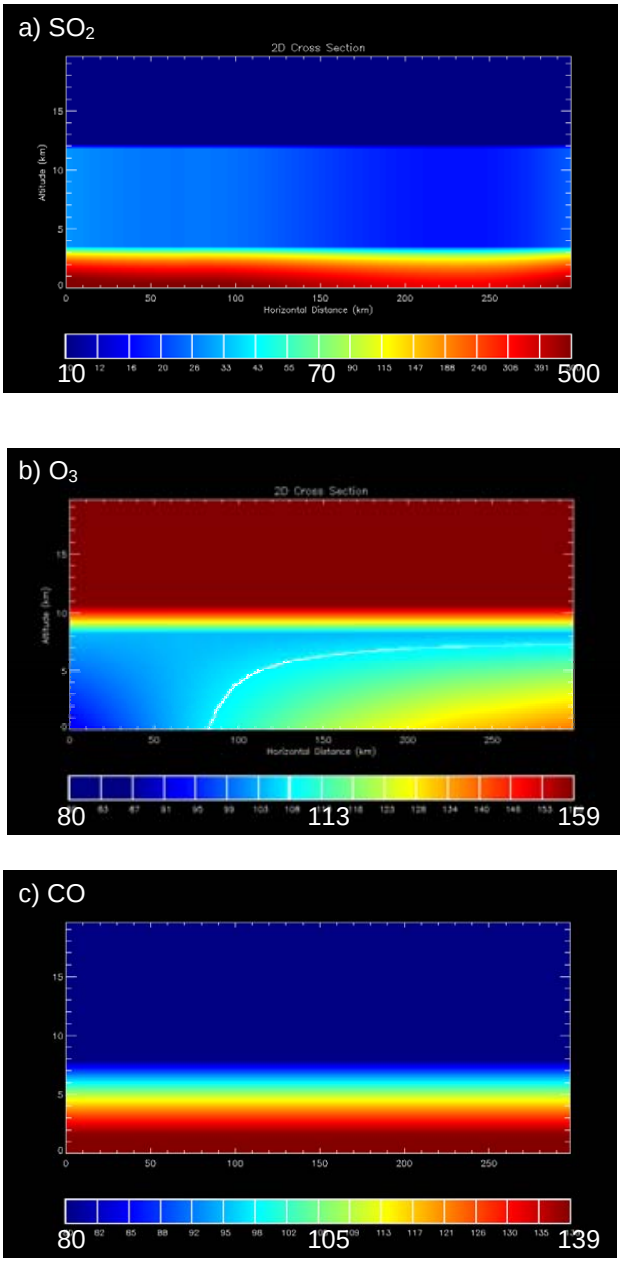

Fig. 3. Initial concentration for chemical compound **(a)** SO_2 (ppbv), **(b)** O_3 (ppbv), and **(c)** CO (ppbv).

the measurements only consider particles with a radius larger than 7 nm, whereas the Aitken mode size interval includes all particles with a radius larger than 6 nm. If a log-normal size distribution is assumed and the upper "tail" of the particles between 6 and 7 nm is removed, the modeled maximum particle concentration at 10.4 km is reduced to 2.4×10^4 cm^{-3}, which corresponds very well with the observations.

The transport of high concentrations of SO_2 and CO from the boundary layer to the top of the cloud can clearly be seen in Figs. 5h and j. For O_3, high concentrations in the free troposphere are usually a result of downward transport of O_3 rich air from the stratosphere. However for the present case, a plume of polluted air with elevated O_3 concentrations close to the surface is transported from the eastern boundary of the model to the free troposphere (cf. Fig. 5i).

The sensitivity of the modeled results to a given parameter or process is judged by the relative difference between the results of the given sensitivity simulation and the corresponding values of the reference run. Model variables used in the comparison include the concentration of Aitken mode sulfate aerosols as well as mixing ratios of CO and SO_2 in the upper troposphere (where observations of aerosol number and CO are available), and surface precipitation, representing several aspects of interest dealing with aerosol microphysics, convective transport of important trace gases, as well as cloud dynamics and microphysics. It is worthwhile noting that our sensitivity simulations are carried out using a

"real" atmospheric case rather than an idealized case of deep convection. The impact of the tested parameters or processes on the interactions among aerosols, cloud droplets, and cloud dynamics thus are included.

4.2 Aerosol microphysics (experiment A, F and H)

In the aerosol module, the accumulation mode sulfate aerosol, which serves as the major part of CCN in the model, mainly originates from coagulation of aerosols and condensation of H_2SO_4 on Aitken mode aerosols. The concentration of Aitken mode aerosols is determined by the rates of aerosol nucleation, condensation of H_2SO_4 and coagulation involving nucleation mode aerosols. In order to explore the sensitivity of the modeled results to these processes, we have designed the A series with coagulation of aerosols, condensation of H_2SO_4, or both coagulation and condensation processes being switched off; the F series with reduced nucleation rate; and the H series with altered or no transfer between the various modes.

It is found that the largest change in Aitken mode number concentration (MNC) at 10.4 km occurs when no coagulation of aerosols or transfer between the different modes is considered, or when the size limit for transfer between the modes is increased (case A1, A2, H1 and H3; Fig. 6a). The

main pathway for Aitken mode aerosol to CCN appears to be coagulation of aerosols, as the concentration of Aitken mode particles in the upper troposphere is higher compared to the reference case in case A1 (Fig. 6a). An increase in the Aitken MNC cannot be seen if only condensation of H_2SO_4 on the aerosols is excluded.

For all A cases as well as the H1 and H2 simulations, not enough CCN are produced from the Aitken mode to sustain a vigorous storm cloud. Thus, the average accumulated precipitation (Fig. 6d) is reduced and vertical wind speeds are substantially weaker than for the reference run results. As a consequence of the weak storm development, the mixing ratios of both CO and SO_2 in the upper troposphere are lower than those of the reference simulation (Figs. 6e and f). The convection is also less developed for the H4 case (10% number transfer between the modes instead of 5%) compared to the reference run and the precipitation and transport of trace gases to the free troposphere is just as weak as in the A simulations.

For the H3 case on the contrary, when particles are allowed to be transferred more rapidly from Aitken to accumulation mode compared to the reference case, the convection becomes more intense. As seen in Fig. 6c the droplet number concentration at 4.0 km is higher in this case than in the reference simulation. Vertical wind speeds are stronger and thus more SO_2 and CO is transported vertically compared to the reference case results. However, the Aitken MNC at 10.4 km is lower compared to the reference case, as more particles are scavenged through nucleation scavenging within the convective cloud in case H3.

A decrease in the aerosol nucleation rate by a factor of two (case F1) somewhat affects the average upper tropospheric Aitken MNC. The convective cloud is less developed in this case compared to the reference case and the transport of trace gases to the free troposphere is weaker. If the nucleation rate is reduced by a factor of 10 (case F2, note that the amount of available H_2SO_4 is the same as in the reference case), the average Aitken MNC at 10.4 km decreases by approximately 20%. Surprisingly, we have found in these model simulations that the decrease in Aitken MNC was not caused by weaker convection and vertical wind speeds, but instead by stronger convection and thus more efficient nucleation and impact scavenging (the average precipitation increases compared to the reference case). When fewer nucleation mode particles are produced, more H_2SO_4 is available, and the growth of nucleation and Aitken mode aerosols to CCN due to condensation becomes very efficient. As seen in Fig. 6b,

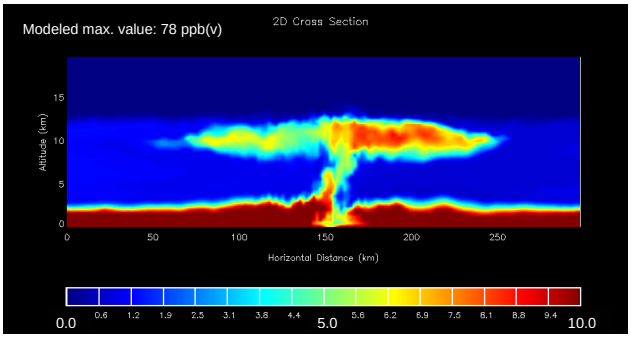

Fig. 5h. Modeled SO_2 concentration (ppbv) after 3 h simulation. The modeled value at 10.4 km is indicated in the figure.

the particle/droplet number concentration at 10.4 km is also higher in the F2 case compared to the reference simulation. The convection is less intense in the F3 case, where the nucleation rate is increased by one order of magnitude. There is a slight change in the Aitken MNC in the free troposphere and also in droplet/ice particle number concentration in this case.

4.3 Aerosol dry deposition (experiment B)

The results of series B (dry deposition, Fig. 7) suggest that the modeled Aitken MNC at 10.4 km is not particularly sensitive to the formulation of dry deposition of aerosols. Modeled average Aitken MNCs differ less than 10% compared to the reference simulation. The convection is slightly stronger in the B1 case where more CCN are available, resulting in increased transport of trace gases to the free troposphere and more precipitation. In the B2 case, the maximum vertical wind speed within the convective cloud is somewhat lower compared to the reference case and the transport of trace gases to the free troposphere is reduced. The maximum

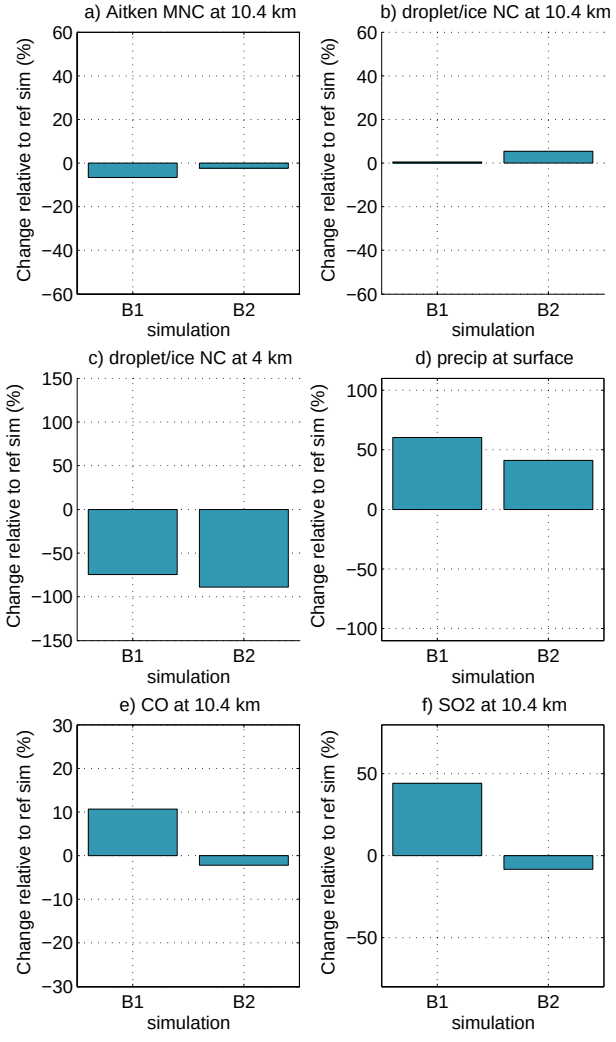

Fig. 7. Same as Fig. 6, but for sensitivity simulation series B.

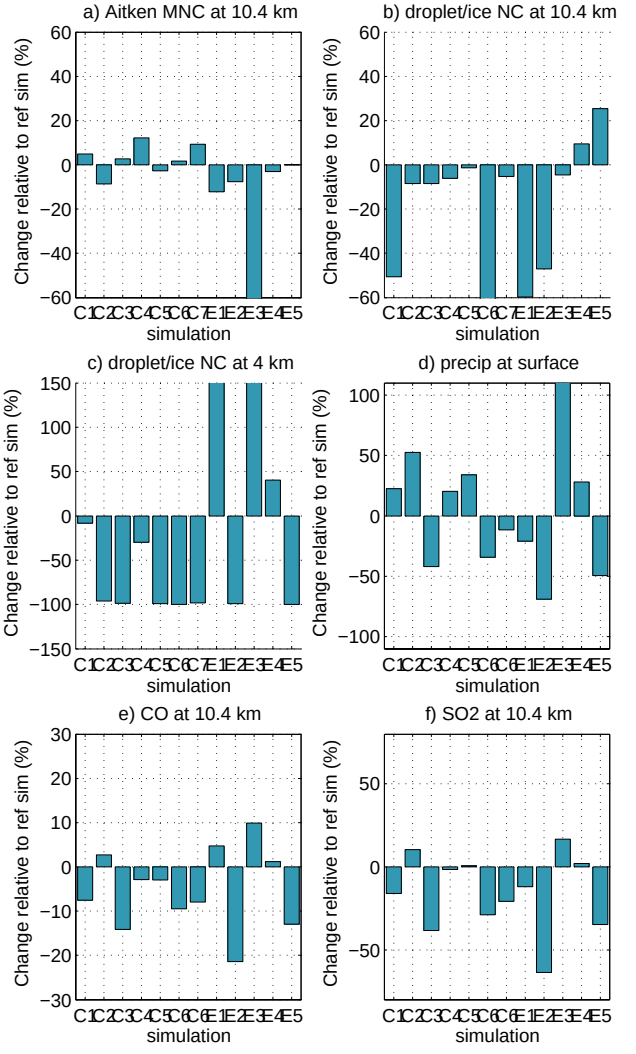

Fig. 8. Same as Fig. 6, but for sensitivity simulation series C and E.

precipitation rate over the model domain is also in general lower than for the reference case throughout the simulation, but the average precipitation rate is higher (the precipitation is more evenly distributed) and the total average precipitation actually increases by ∼40%.

4.4 Aerosol scavenging processes (experiment C and E)

Once the cloud starts to develop, the scavenging of aerosols via nucleation scavenging (aerosols activated to form cloud droplets) or by impact scavenging (aerosols removed by precipitating particles) will influence the upper tropospheric concentration of aerosols. We have tested the sensitivity of the modeled results to various setups in the scavenging calculations.

In sensitivity series C (Fig. 8), different collision coefficients (cases C1 to C4 and C6 to C7) along with additional impact scavenging of BC aerosols (case C5) are tested. The change in average Aitken MNC in the free troposphere is the largest when the impact scavenging is removed completely (C4). However, even in this case, the change in Aitken MNC is only slightly more than 10% compared to the reference case. Despite the small changes in Aitken MNC, the shape of the cloud clearly differs among the C cases and the reference simulation (due to the altered number of available CCN), resulting in a change of the average precipitation amount by up to 50%. In addition, as can be seen in Fig. 8c, the average droplet concentration at the cloud base (which is mainly affected by the number of CCN) is changed by up to 100%.

It is interesting to note that for the two cases with lower collision efficiency than in the reference case, the convection turns out to be less intense with reduced vertical wind speeds. Accordingly, the concentration of trace gases at 10.4 km is lower; the difference is up to 15% for CO and up to 40% for SO_2. The insensitivity of upper tropospheric Aitken MNCs to different treatments of impact scavenging is not entirely a surprise. Kinetically speaking, the collection efficiency of

aerosols, particularly those in the size range of Aitken mode, by precipitating particles is very low (Table 1; see also Pruppacher and Klett, 1997).

The usage of a new aerosol module in the CRM (cf. Sect. 2.2) introduces the possibility to calculate size-dependent nucleation of cloud droplets. This method has been compared with the method using an empirically derived formula in experiment E1. The sensitivity of the size-dependent nucleation on the calculation of the critical activation radius is tested in series E2–E5. In the case where the critical activation radius is 10 times smaller compared to the reference case (E3), a larger fraction of Aitken mode particles are considered as CCN and thus scavenged in the nucleation of cloud droplets. Hence, the average Aitken MNC at 10.4 km decreases by almost 90%. For the other E cases, the changes in average Aitken MNC is small. The shape and the extent of the cloud are clearly different for all E cases compared to the reference case and the average precipitation rate either increases (E3 and E4) or decreases (E1–E2, E5) by 20% or more. In both the E1 and E2 cases there is also a substantial decrease in the average droplet/particle concentration at 10.4 km. This suggests the empirical method commonly used in cloud-resolving models for calculating nucleation of cloud droplets underestimates the nucleation-scavenging rate of aerosol. For the E3 case, where the convection is more intense compared to the reference case, there is a considerably stronger transport of trace gases to the free troposphere.

In the E5 case, the sulfate aerosols are assumed to consist of SO_4 instead of $(NH_4)_2SO_4$, to test the sensitivity of the modeled results to the chemical composition of the aerosol. The critical radius for activation is higher in this simulation, and fewer aerosols are available as CCN. The convection is less intense, the average precipitation amount is lower compared to the reference simulation and the vertical wind speed is reduced. However, the average Aitken MNC at 10.4 km is almost unchanged. This sensitivity simulation shows a potential impact of different aerosol compositions on cloud development and precipitation amounts. In a future model version, it would be desirable to include additional aerosol compounds such as ammonium and nitrate as prognostic variables.

4.5 Initial distribution of aerosols (experiment D)

The sensitivity of the model to the initial distribution and concentration of aerosols is tested in experiments D1–D8 (Fig. 9). The modeled average precipitation increases substantially in case D3 and D6 (where the decrease of the aerosol number concentration with height is either removed or reduced) whereas it decreases in cases D2, D4, D5 and D7. For cases D1, and D8 the change is small. In a global model sensitivity study of anthropogenic aerosol impact on convective warm precipitation, Nober et al. (2003) obtained local changes of up to 100% in precipitation amount and related latent heat release. The result in the present study of

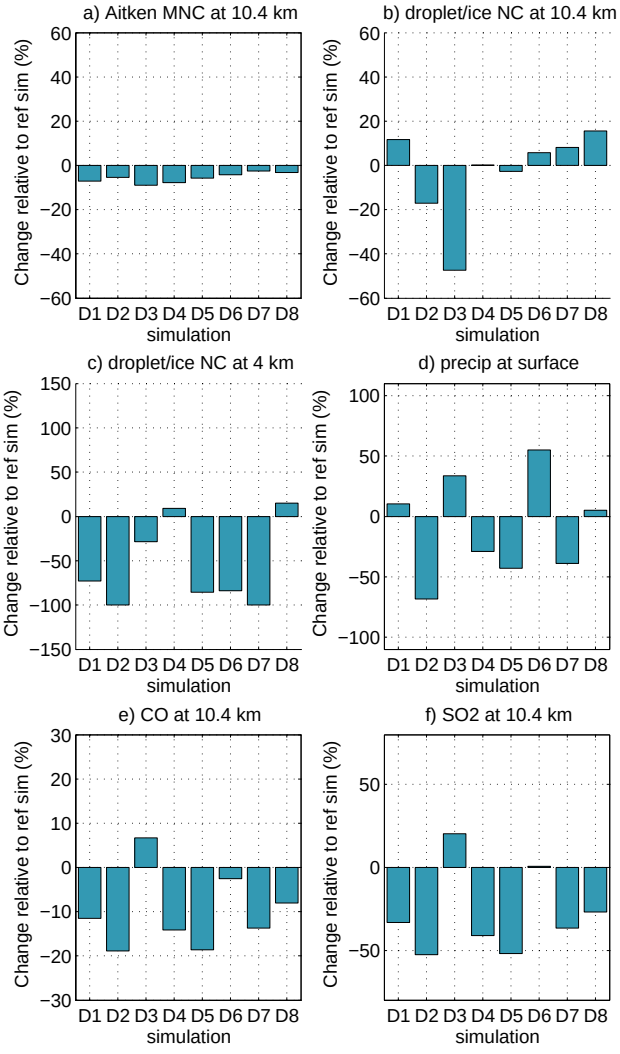

Fig. 9. Same as Fig. 6, but for sensitivity simulation series C and E.

a maximum 50–70% change in precipitation is in agreement with the study by Nober et al. (2003).

In simulations D2 and D5, where the particles are fewer or smaller compared to the reference simulation, the convective activity is limited and vertical wind speeds are low. In case D7, where more Aitken mode particles are available initially, the convection is also less developed compared to the reference case because of inefficient particle growth by coagulation of aerosols and condensation of H_2SO_4 due to the high particle number. Compared to the reference case, average trace gas concentrations at 10.4 km decrease up to 20% for CO and 45% for SO_2. However, the Aitken MNC at 10.4 km is not substantially altered by the change in precipitation and vertical wind speeds within the cloud. Differences are less than 10%.

The fact that the Aitken MNC at 10.4 km after 3 h of simulation is almost unaffected by the choice of initial aerosol profile suggests that the chemical and physical conversions

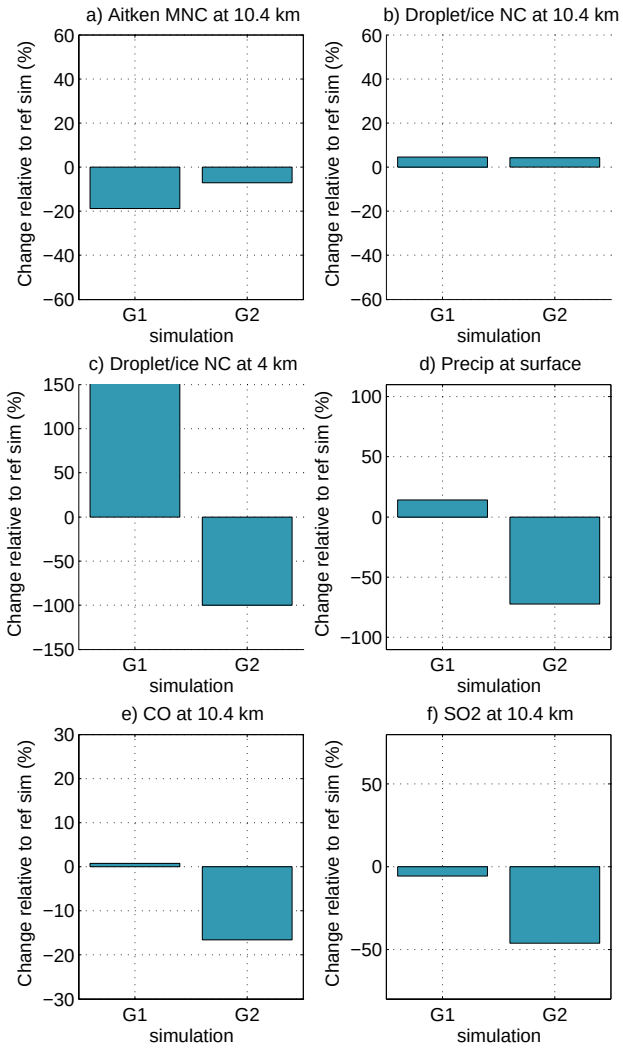

Fig. 10. Same as Fig. 6, but for sensitivity simulation series G.

taking place within a convective cloud are very fast, and the changes in Aitken mode aerosol properties in the upper troposphere are mainly influenced by these rapid conversions, not the initial conditions. Already at an early stage of the simulation, accumulation mode and Aitken mode aerosols are scavenged by intense precipitation. Hence, the concentration of particles after 3 h of simulation is more determined by the formation and growth of small particles than by the initial concentration of CCN.

It is also interesting to note that, despite the small change in Aitken MNC, the average droplet/particle number concentration at 10.4 km changes by over 10% in a majority of the D simulations. The explanation may be that the ice nuclei number is not calculated using the explicit aerosol module (cf. Sect. 2.2). Hence, processes that will have a crucial influence on the number of ice crystals formed are e.g. updraft velocity, relative humidity and temperature and not the Aitken MNC.

Changing the initial distribution and concentration of aerosols is one way to affect the number of available CCN within the model domain. The radiation-type of lateral boundary conditions adopted in the current model setup actually maintains a supply of aerosols from the inflow boundary to the rest of the model domain (the gradient of the normal flux of variables at the inflow lateral boundary is set to zero). This assumption is equal to assuming a zero-gradient plume resident just outside the inflow boundary. Another way to simulate the external influence on the number of available CCN in the model is to apply an added flux of aerosols flowing into the domain through a different setup of the lateral boundary conditions, equivalent to assuming a given concentration gradient of a plume. This could result in that more aerosols are available as CCN during the simulation, and hence that the strength of the convection is altered. For future studies, the effect of an external supply of aerosols on the modeled results will be examined.

4.6 Initial concentration of aerosol precursor (experiment G)

The modeled temperature, relative humidity and the H_2SO_4 concentration determine the simulated nucleation rate of aerosols. Nucleation mode particles grow rapidly to become Aitken mode and then accumulation mode particles and they may hence be a major source of CCN. The G series of experiments are designed to examine the sensitivity of the model to the initial H_2SO_4 concentration (Fig. 10). The H_2SO_4 concentration will determine how many nucleation mode particles that are formed initially (if H_2SO_4 is a limiting factor), as well as how much H_2SO_4 that is available for condensation at the beginning of the simulation.

For the G1 case, where more H_2SO_4 is available initially, the convection is more intense compared to the reference case and more particles are scavenged by precipitation, resulting in a lower average Aitken MNC at 10.4 km. The average accumulated precipitation over the model domain is similar as for the reference case, but the precipitation is more widespread and the maximum precipitation is substantially lower. There is also a significant increase in the droplet concentration close to the cloud base.

For the G2 case, less H_2SO_4 is available at the beginning of the simulation and fewer nucleation mode particles are formed. The convection is less intense and both the average and maximum precipitation rate are substantially lower. The transport of Aitken mode particles to the free troposphere is almost the same, or somewhat weaker, compared to the reference case. Lower vertical wind speeds also result in lower trace gas concentrations at 10.4 km. For both G cases, the total condensed H_2SO_4 after 3 h of simulation is almost unaffected.

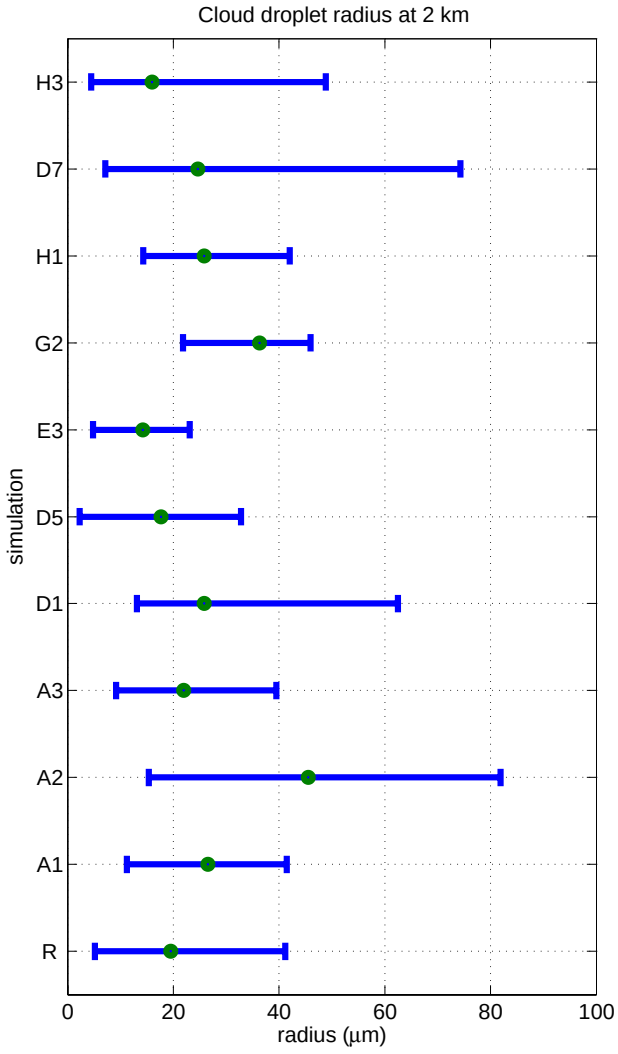

Fig. 11a. Average (both horizontally and over 3 h of simulation) effective cloud droplet radius at cloud base (2.0 km). Also shown in the figure are the maximum and minimum horizontally averaged effective cloud droplet radius simulated over the 3-h period.

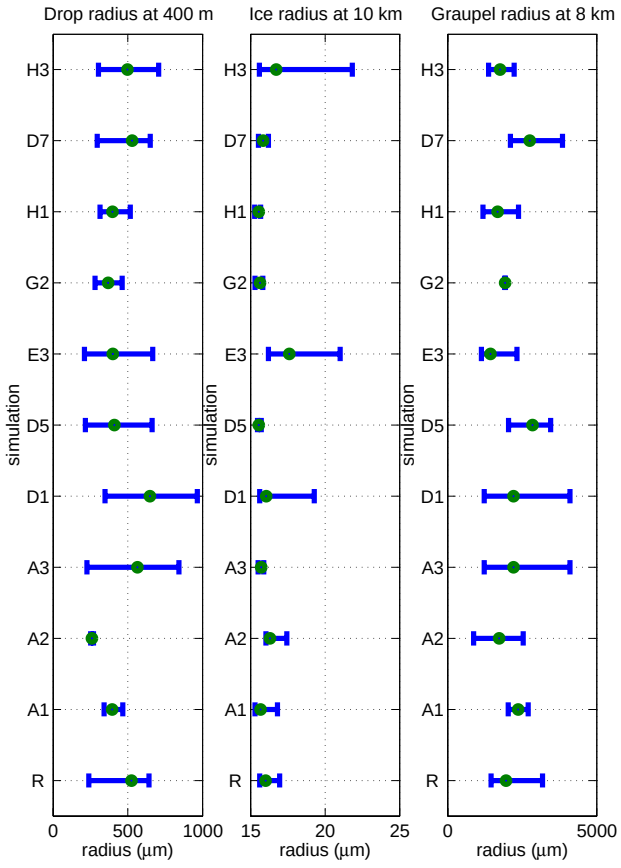

Fig. 11b. Average (both horizontally and over 3 h of simulation) effective rain drop radius, ice particle radius and graupel radius at 400 m, 10 km and 8 km, respectively. Also shown in the figure are the maximum and minimum horizontally averaged effective radii simulated over the 3-h period.

4.7 Hydrometeor properties

Besides the upper tropospheric distributions of aerosols and chemical species, the characteristics of the cloud droplets and precipitation particles can also be changed by altered descriptions of physical and chemical processes. Figure 11 shows various hydrometeor characteristics for a selected number of sensitivity simulations (the selected cases are the ones where a clear difference in the Aitken MNC at 10.4 km compared to the reference case was obtained, as well as the case where the initial Aitken MNC was increased by a factor of 100).

Close to the cloud base (at 2 km), the average drop radius over 3 h of simulation is approximately 20 μm for the reference simulation. The largest change in cloud droplet size is obtained in the A2 simulation where no coagulation of aerosols or condensation of H_2SO_4 is considered. In this case, the average droplet radius is ~45 μm. Fewer particles are available as CCN and hence the existing droplets may grow larger.

The smallest cloud droplets are found in the E3 and H3 cases. In both these simulations, more CCN are available compared to the reference simulation and the average droplet radius decreases to 14 and 16 μm, respectively. The average drop radius for rain at the lowest model level (400 m) is also smaller in the E3 and H3 simulations. Compared to the reference case, the falling raindrops below the cloud decrease by 37% and 7%, respectively. Consistently with this result, rain drops higher up in the cloud (e.g. at 7.2 km), are in the E3 and H3 simulations smaller (23% and 5%) than in the reference simulation and graupel particles at 8 km altitude are also smaller.

At the top of the cloud, the simulated ice particles are actually slightly larger over the 3 h simulation period in the E3 and H3 cases compared to the reference case. More water vapor is transported to the top of the cloud, the vertical

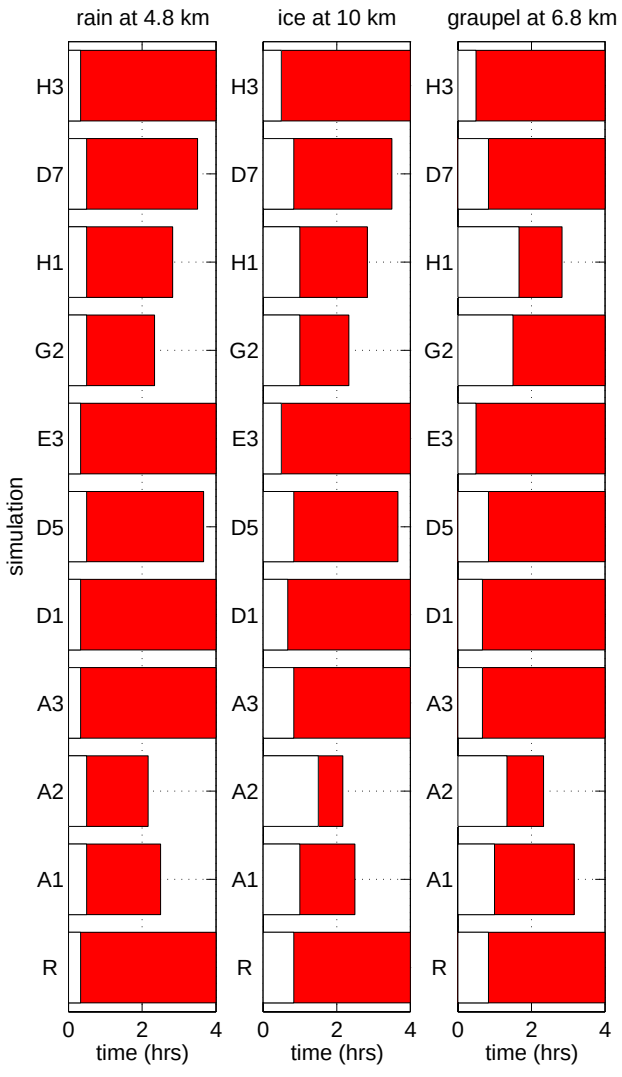

Fig. 12. Time for onset and termination of rain, ice and graupel formation at 4.8 km, 10 km and 6.8 km, respectively.

wind speed is higher and the ice particles can grow more efficiently. This result is in contrast with the findings by e.g. Sherwood (2002) who using satellite-retrieved data found a negative correlation between aerosol optical depth and ice crystal radius at the top of convective clouds.

Previous model studies have indicated that convective precipitation may be suppressed as a result of higher atmospheric aerosol loading (e.g. Phillips et al., 2002). Andreae et al. (2004) observed substantial changes in precipitation amount and precipitation characteristics during periods of heavy smoke over the Amazon basin. However, no firm conclusion could be drawn if the increased particle amount resulted in a net positive or a net negative precipitation change. The onset of the rain occurs at about the same time in all of the simulations (Fig. 12). It starts somewhat later in simulations A1, A2, D5, G2, H1 and D7 than in the reference simulation. In all of the sensitivity simulations where the onset of the rain is later compared to the reference simulation, there are generally fewer particles available to constitute CCN, the cloud is less developed, and the rainfall also terminates sooner. One exception is the D7 case, where actually more Aitken mode particles are available at the beginning of the simulation (a concentration which is not unrealistic for polluted urban air). In this case, the particles with smaller sizes are so numerous that they cannot grow efficiently to become CCN. For the D1, E3 and H3 simulations, where more CCN are available throughout the simulation and the convection is more intense, the graupel and ice formation occur earlier than in the reference simulation. The amount of surface precipitation is also substantially larger compared to the reference case (cf. Figs. 6, 8 and 9). Another interesting result for the D1, E3 and H3 simulations is that the variability in the ice particle radius during the integration is much larger compared to the other cases (cf. Fig. 11b). The reason is most likely that the updraft velocity is stronger when the convection is more intense, which allows a more efficient growth of the ice crystals, and also that more ice particles can form in the upper part of the cloud than in the other cases. As a result, a large variability in the ice particle radius is obtained.

5 Conclusions

The role of convection in introducing aerosols and promoting the formation of new particles to the upper troposphere has been examined using a cloud-resolving model coupled with an interactive explicit aerosol module. The size distribution of aerosols is an important factor in determining the aerosols' fate within the convective cloud. Accumulation mode aerosols, as ideal CCN, are removed almost completely by the heavy precipitation within the modeled storm cloud. Nucleation mode aerosols grow fast due to coagulation of aerosols and condensation of H_2SO_4 and are in addition efficiently scavenged by falling precipitating drops. Hence, there is only a small part of the population (concentrations of a few particles per cm^3) that reaches the free troposphere. Aitken mode aerosols are to some extent removed by nucleation scavenging, but the particles in the lower part of the size range are not efficient as CCN and are thus transported to the top of the storm cloud. Once in the free troposphere, Aitken mode particles may grow over time and are eventually available as effective CCN and IN. In the model simulations, up to 10% of the Aitken mode particles in the boundary layer reach the anvil of the cloud.

A set of 34 sensitivity simulations performed, using various physical and chemical settings as well as different initial aerosol concentrations and chemical compositions, indicates that critical processes in the model causing a substantial change in the upper tropospheric Aitken MNC (between ten and several hundred percent) are coagulation of aerosols, condensation of H_2SO_4, nucleation scavenging, nucleation

of aerosols, and also the transfer of aerosol mass and number between different aerosol bins. Less important processes are dry deposition, impact scavenging, and the initial vertical distribution and concentration of aerosols.

Coagulation of aerosols is the major pathway in the model for production of Aitken mode particles. When this process is shut off, the production of CCN is reduced by several orders of magnitude. No vigorous convection is initiated as a result, which means that condensation of H_2SO_4 onto particles cannot alone produce enough new CCN. Omitting condensation in the model also results in a slower growth of small particles and the convection becomes weaker than in the reference simulation, but not as weak as if coagulation of aerosols is left out of the model.

The simulation of nucleation scavenging in the present model version is size-dependent, and the calculation of the critical radius for activation of particles appears to be of major importance to the modeled results. If the critical activation radius is decreased by a factor of 10 in the model, the characteristics of the cloud becomes substantially different and the Aitken MNC in the free troposphere decreases by nearly 90% compared to the reference case. In addition, use of the empirical method for the calculation of nucleation scavenging leads to a decrease of the Aitken MNC at 10.4 km by more than 10%.

The present study shows that the parameterized rate of nucleation clearly affects both the upper tropospheric Aitken MNC and ice particle/droplet number concentration (and hence the overall cloud development). Atmospheric nucleation is still a poorly known process. For instance, it has been shown that observed nucleation rates frequently exceed those predicted by sulfuric acid-water nucleation theories and laboratory measurements (Weber et al., 1997; Covert et al., 1992; Viisanen et al., 1997; Clarke et al., 1998; Kulmala et al., 1998b; O'Dowd et al., 1999; Birmili and Wiedensohler, 2000).

Due to the possible overlap of different modes of aerosols, "remapping" aerosol size distribution by allowing transfer of aerosols from one mode to another is a common and necessary procedure in aerosol models of modal type. The set of sensitivity simulations aiming at the transfer of particles between the different sulfate modes indicate that certain degree of cautiousness should be applied for this procedure. Even a relatively small change in assumed mass transfer limit (from 5% to 10% in the related sensitivity tests) might cause significant changes in modeled results including the upper tropospheric redistributions of Aitken mode aerosols and chemical compounds. In addition, the transfer of aerosol particles is dependent on the calculation of the diameter of average mass (which determines the shape of the distribution function) and an error in this calculation by a factor of two causes substantial changes in the cloud development.

Previous studies (Sherwood, 2002; Phillips et al., 2002) have suggested a negative correlation between ice crystal size at the top of a convective cloud and aerosol loading close to the ground. In the present study, the simulated ice particles in the free troposphere are actually somewhat larger if the aerosol concentration in the boundary layer is high. However, the average radius of cloud droplets, rain droplets and graupel particles becomes smaller. In the present model, the aerosol module does not predict the number of available particles for ice nucleation (cf. Sect. 2.1). Hence, the growth of ice crystals in the upper part of the cloud is more dependent on the vertical velocity, temperature and most importantly water vapor supply, than on the aerosol concentration in the boundary layer. For future studies, the number of available ice nuclei will just as the number of CCN be predicted by the aerosol module.

A noticeable variation in the development and characteristics of the convection has been found in all of the sensitivity simulations. In order to sustain a vigorous storm cloud, the supply of CCN must be continuous over a considerably long period during the simulation. Hence, the treatment of the growth of particles is in general much more important than the initial aerosol concentration itself. Another alternative for sustaining the CCN concentration within the model area could be by a maintained supply of aerosols from outside the model domain. However, it is also crucial that enough CCN are available at the beginning of the simulation for the actual initiation of the convection. Otherwise, the cloud development becomes slow, vertical wind speeds weak and precipitation amounts low. In addition, although not having a substantial effect on the upper tropospheric Aitken MNC, changing the initial atmospheric aerosol concentration results in a change in surface precipitation and vertical wind speeds of up to 50–70%, and this is consistent with a recent study using the same cloud-resolving model but simpler aerosol module (Wang, 2004a, b). No straightforward relationship between the initial atmospheric aerosol loading and the amount of precipitation could be found, but in case of a continuously higher supply of CCN, the total surface precipitation amount generally increases. These results all suggest further research on the effect of anthropogenic aerosol on convective clouds and precipitation.
